For example, in a telephone line, if the line is carrying more than approximately 40 dB of signal, distortion of the signals passing through the line will occur. This limitation in the line capacity is often referred to as the copper capacity of the line. The standards which were developed for determining the capacity of a line were developed based on the propagation properties of the medium which carries the signals. The properties of the medium can vary from different geographic regions. In Europe, for example, the properties of the medium for a telephone line are generally better than in the United States. A 10% difference in capacity of a line carrying a 40 dB signal between the European and American standards is not significant, and the increased cost of implementing the European standards is not justified. As a result, in Europe telephone companies have recently discontinued their use of the higher capacity copper wire lines. As a result, the need to transmit signals over telephone lines with greater capacities has led to the development of telephone lines which can transmit signals at greater capacities. One such line which is capable of transmitting signals at greater capacities is the T-carrier system. The T-carrier system is an ISDN circuit transmission system. In the T-carrier system, signals are sent as signal frames which contain up to 64 separate signal channels. The frames are transmitted over a copper wire which is divided into 128 different segments, and each of the 128 segments is capable of carrying a signal channel. The capacity of the lines used in the T-carrier system is generally
